Fig. 3. Radial velocity variations. Solid circles show the individual radial velocity measurements as a function of barycentric Julian date (BJD); the black solid line is the best-fitting photodynamical model to the combined Kepler and radial velocity data. Thin gray, blue, and red lines show the individual components of the fit, which includes a radial velocity drift modeled as a quadratic function of time and radial velocity variations due to planets b and c. The drift is attributed to a third, massive companion in a wide orbit.

Gravitational-Wave Limits from Pulsar Timing Constrain Supermassive Black Hole Evolution

R. M. Shannon,1,2* V. Ravi,1,2,4† W. A. Coles,3 G. Hobbs,4 M. J. Keith,3 R. N. Manchester,4 J. S. B. Wyithe,2,4 M. Bailes,4 N. D. R. Bhat,4,5 S. Burke-Spolaor,6 J. Khoo,1,7 Y. Levin8 S. Osłowski,4 J. M. Sarkissian,9 W. van Straaten,11 J. P. W. Verbiest9,10 J.-B. Wang1,11

The formation and growth processes of supermassive black holes ( SMBHs ) are not well constrained. SMBH population models, however, provide specific predictions for the properties of the gravitational-wave background ( GWB ) from binary SMBHs in merging galaxies throughout the universe. Using observations from the Parkes Pulsar Timing Array, we constrain the fractional GWB energy density ( Ω GWB ) with 95% confidence to be Ω GWB = (3 ± 1) × 10−9 (where H 0 is the Hubble constant) at a frequency of 2.8 nanohertz, which is approximately a factor of 6 more stringent than previous limits. We compare our limit to models of the SMBH population and find inconsistencies at confidence levels between 46 and 91%. For example, the standard galaxy formation model implemented in the Millennium Simulation Project is inconsistent with our limit with 50% probability.

Supermassive black holes ( SMBHs ), with masses between 106 and 109 solar masses, are observed to exist at the centers of all massive galaxies in the nearby universe and to have masses that scale closely with properties of their hosts (1, 2). Together, these phenomena...
suggest that the growth processes of SMBHs and of their host galaxies are connected. Galaxies, and groups of galaxies, are embedded in even larger dark matter halos, which form and evolve through the hierarchical merging of smaller dark matter halos and galaxies (3, 4). Galaxy mergers are expected to result in binary SMBHs (5, 6), which, though notoriously difficult to observe via electromagnetic signatures, are expected to be the strongest sources of gravitational waves in the universe (7). The universality of galaxy mergers implies the existence of a gravitational-wave background (GWB) from binary SMBHs (8, 9).

The GWB is manifested as a red-noise process in pulse arrival time measurements from pulsars (10). Pulsar timing array groups search for evidence of the GWB in radio-frequency observations of millisecond pulsars, which have rivaled evidence of the GWB in radio-frequency observations (8). These authors contributed equally to this work.

The GWB is parameterized by its wave amplitude spectrum, $h_\alpha(f) = A(f/f_\alpha)^{2/3}$, where $f$ is the received gravitational-wave frequency, $f_\alpha$ is a reference frequency of one cycle per year, and $A$ is the characteristic amplitude that defines the strength of the GWB. The fraction of the critical energy density of the universe, per logarithmic frequency interval ($\Omega_{GW}$), of the GWB is $\Omega_{GW}(f) = (2\pi^2/3H_0^2)A^2(f/f_\alpha)^{-2}$ $(10)$, where $H_0$ is the Hubble constant, which we assume to be 73 km s$^{-1}$ Mpc$^{-1}$.

Recent observations by two separate pulsar timing array groups have been analyzed to find $A < 6 \times 10^{-15}$ (12) and $< 7 \times 10^{-15}$ (13) with 95% confidence.

We have been monitoring pulse arrival times from 20 millisecond pulsars with the 64-m Parkes Telescope as part of the Parkes Pulsar Timing Array (PPTA) project (14) and previous observing programs (15). We extended the timing baseline of this data set by including publicly available observations from the Arecibo observatory (16). A detection of the GWB relies on measuring correlations between residual pulse arrival times for multiple pulsars with different angular separations on the sky. Within the PPTA timing program, there are presently too few pulsars with sufficient timing precision and data span to make an unambiguous detection of the GWB feasible (17). We instead use observations of six pulsars with the lowest noise levels over the longest observing spans to constrain the GWB amplitude (18) (Fig. 1).

Our limit on the strength of the GWB was computed in two stages (19). For each pulsar $j$, we first estimated the power spectral density $P_j(f)$ of the residual pulse arrival times after a fit for a pulsar model (20) at frequencies $f$ that are harmonics of $1/T_{\text{obs}}$ where $T_{\text{obs}}$ is the observing span for the pulsar. A prewhitening method (21) was used in the spectral estimation to eliminate spectral leakage and to provide nearly independent spectral estimates, even if red-noise signals, such as those expected from the GWB, are present. We form a detection statistic (DS) from the power spectra

$$A^2 = \sum_j \int P_j(f)g_j(f)M_j(f)^2\sum_i \int g_i(f)M_i(f)^2$$

(1)

where $g_j(f)$ is the shape of the power spectrum induced by the GWB and $M_j(f)$ is a model of the observed spectrum (Fig. 1). The DS $A^2$ combines individual spectral estimates $P_j(f)$ to form a conservative estimate of the square of the characteristic amplitude of the GWB ($A^2$). If the spectral models are correct, a DS of the form in Eq. 1 provides an estimate of $A^2$ with a maximal signal-to-noise ratio. To set a limit on $A$, we compared the observed value of the DS with distributions of the

![Fig. 1. Observed power spectra of the residual postfit arrival times and models of these spectra for the PPTA pulsars used to set the limit on the GWB amplitude. The observed power spectra (PS), $P_j$, for the pulsars are shown as black lines, along with the models of the PS, $M_j = W_j + G_j + R_j$ (shown as purple lines). The models contain a white component ($W_j$, gray lines), a common GWB component $G_j$ (pink lines), and, for PS J1713+0747, an additional red-noise term $R_j$ (red line). The PS models were used only for the determination of the weights in the calculation of the detection statistic. The green curves show what the PS would look like (on average) in the presence of a Gaussian GWB with amplitude $2.4 \times 10^{-25}$. The names of the pulsars are given in the top-right corners of each panel.](http://science.sciencemag.org/abs/images/342/6168/342_6168.jpg)
As a specific example for how pulsar timing array observations can affect models of SMBH formation and growth, we calculated the level of $\Omega_{GW}(f_{\text{PPTA}})$ (24) expected from a semi-analytic galaxy formation model (4) implemented within the Millennium (27) and Millennium-II (28) dark matter simulations. This model, in which SMBHs are seeded in every galaxy merger remnant at early times and grow primarily by gas accretion triggered by galaxy mergers, represents the standard paradigm of galaxy and SMBH formation and evolution. The model accurately reproduces the luminosity function of quasars at $z < 1$ corresponding to the epoch predicted to dominate the GWB (8, 25, 26). The range of predictions for $\Omega_{GW}(f_{\text{PPTA}})$ results from the finite observational sample of measured SMBH and bulge mass pairs (2), which is used to tune the model, but neither accounts for uncertainties in the observed galaxy stellar mass function (4) nor in the nature of the relations between SMBH masses and bulge masses (2). Assuming a non-Gaussian GWB, the probability that this prediction for $\rho_{GW}(\Omega_{GW})$ will be inconsistent with the PPTA data is 49%.

A complementary prediction for the strength of the GWB comes from an independent model for SMBH growth at late times (29). This model examines the growth mechanisms of SMBHs in cluster and void environments through mergers and gas accretion. The model is inconsistent with the PPTA data at the 61% confidence level.

The PPTA constraints on the GWB show that pulsar timing array observations have reached a sufficient level of sensitivity to test models for the binary SMBH population. The highest galaxy merger rate that is consistent with the observed evolution in the galaxy stellar mass function (25) is inconsistent with our limit. We exclude 46% of the parameter space of a model that surveys empirical uncertainties in the growth and merger of galaxies and black holes (26); therefore, our results reduce these uncertainties. Although the PPTA limit excludes only 49 and 61% of realizations of the GWB from two galaxy and SMBH evolution models, these models are open to refinement. For example, these models do not include SMBH formation mechanisms consistent with high-redshift quasar observations (30), nor do
they reproduce the observed larger scatter and possibly higher normalization in SMBH-galaxy scaling relations for the most massive SMBHs (\(J_2\)). Other physical effects will also be built into the next generation of GWB models. For example, recent numerical simulations of massive galaxy mergers predict binary SMBHs with eccentricities ranging between 0.1 (\(J_1\)) and 0.9 (\(J_2\)). If binaries radiating gravitational waves at frequencies relevant to pulsar timing arrays are considerably eccentric or predominantly evolving under environmental interactions (33), the spectral shape of \(\Omega_{GW}(f)\) may differ from current predictions (34).

Strain-Induced Ultrahard and Ultrasable Nanolaminated Structure in Nickel
X. C. Liu,* H. W. Zhang,* K. Lu1,2†

Heavy plastic deformation may refine grains of metals and make them very strong. But the strain-induced refinement saturates at large strains, forming three-dimensional ultrafine-grained (3D UFG) structures with random orientations. Further refinement of this microstructure is limited because of the enhanced mobility of grain boundaries. Very-high-rate shear deformation with high strain gradients was applied in the top surface layer of bulk nickel, where a 2D nanometer-scale laminated structure was induced. The strongly textured nanolaminated structure (average lamellar thickness of 20 nanometers) with low-angle boundaries among the lamellae is ultrahard and ultrastable: It exhibits a hardness of 6.4 gigapascal—which is higher than any reported hardness of the UFG nickel—and a coarsening temperature of 40 kelvin above that in UFG nickel.

Metals can be strengthened by introducing more grain boundaries (GBs) via grain refinement (\(J_1\), \(J_2\)) or alternatively by generating more dislocations (3). Remarkable hardening in metals and alloys induced through heavy plastic deformation originates from both mechanisms: Grains are refined to the sub-micrometer or nanometer scales, and stored dislocation density is pumped up by orders of magnitude. However, as the strains exceed values between 5 and 30, saturation in grain refinement leads to steady-state three-dimensional (3D) ultrafine-grained (UFG, sub-micrometer–sized) structure with random orientations (4–6). Further increases in strain, however, can lead to grain coarsening and dislocation annihilation (7, 8). As grain size drops into the submicro- or nanoscale, GB migration becomes so pronounced that grains coarsen even at ambient temperature (9). Because the dislocation multiplication from straining is balanced by the dislocation annihilation due to GB migration, strain-induced structural evolution ceases, and dislocation density reaches its limit, which in heavily deformed metals is typically \(\sim 10^{12}\) m\(^{-2}\).

Among various processing parameters of plastic deformation, strain rate, deformation temperature, and strain gradient seem most relevant to dislocation multiplication and, hence, to structure refinement or reduction of boundary spacing, which governs strength and other mechanical properties of materials. Deformation at high strain rates or at low temperatures may suppress dislocation annihilation kinetics and facilitate forming more GBs or dislocation boundaries. For instance, when nickel (Ni) is compressed at a rate

Editor's Summary

Testing Black Holes

Gravitational waves, predicted by General Relativity, are expected to be produced when very massive bodies, such as black holes, merge together. Shannon et al. (p. 334) used data from the Parkes Pulsar Timing Array project to estimate the gravitational wave background produced by pairs of supermassive black holes (those with masses between $10^6$ and $10^{11}$ that of the Sun) in merging galaxies. The results can be used to test models of the supermassive black hole population.
